Federated Learning via Over-the-Air Computation

Kai Yang, Student Member, IEEE, Tao Jiang, Student Member, IEEE, Yuanming Shi, Member, IEEE, and Zhi Ding, Fellow, IEEE

Abstract—The stringent requirements for low-latency and privacy of the emerging high-stake applications with intelligent devices such as drones and smart vehicles make the cloud computing inapplicable in these scenarios. Instead, edge machine learning becomes increasingly attractive for performing training and inference directly at network edges without sending data to a centralized data center. This stimulates a nascent field termed as federated learning for training a machine learning model on computation, storage, energy and bandwidth limited mobile devices in a distributed manner. To preserve data privacy and address the issues of unbalanced and non-IID data points across different devices, the federated averaging algorithm has been proposed for global model aggregation by computing the weighted average of locally updated model at each selected device. However, the limited communication bandwidth becomes the main bottleneck for aggregating the locally computed updates. We thus propose a novel over-the-air computation based approach for fast global model aggregation via exploring the superposition property of wireless multiple-access channel. This is achieved by joint device selection and beamforming design, which is modeled as a sparse and low-rank optimization problem to support efficient algorithms design. To achieve this goal, we provide a differenceof-convex-functions (DC) representation for the sparse and lowrank function to enhance sparsity and accurately detect the fixed-rank constraint in the procedure of device selection. A DC algorithm is further developed to solve the resulting DC program with global convergence guarantees. The algorithmic advantages and admirable performance of the proposed methodologies are demonstrated through extensive numerical results.

Index Terms—Federated learning, over-the-air computation, edge machine learning, sparse optimization, low-rank optimization, difference-of-convex-functions, DC programming.

I. INTRODUCTION

The astounding growth in data volume promotes widespread artificial intelligent applications such as image recognition and natural language processing [1], thanks to the recent breakthroughs in machine learning (ML) techniques particularly deep learning, as well as the unprecedented levels of computing power [2]. Nowadays the typical machine learning procedure including the training process and the inference process, is supported by the cloud computing, i.e., a centralized cloud data center with the broad accessibility of computation, storage and the whole dataset. However, the emerging intelligent mobile devices and high-stake applications such as drones, smart vehicles and augmented reality,

call for the critical requirements of low-latency and privacy. This makes the cloud computing based ML methodologies inapplicable [3]. Therefore, it becomes increasingly attractive to possess data locally at the edge devices and then performing training/inference directly at the edge, instead of sending data to the cloud or networks. This emerging technique is termed as edge ML [4]. The main bottleneck is the limited computation, storage, energy and bandwidth resources to enable mobile edge intelligent services. To address this issue, there is a growing body of recent works to reduce the storage overhead, time and power consumption in the inference process using the model compression methods via hardware and software co-design [5], [6]. Furthermore, various advanced distributed optimization algorithms [7], [8], [9], [10], [11] have been proposed to speed up the training process by taking advantages of the computing power and distributed data over multiple devices.

Recently, a nascent field called *federated learning* [10], [11], [12], [13], [14] investigates the possibility of distributed learning directly on the mobile devices to enjoy the benefits of better privacy and less network bandwidth. However, a number of challenges arise to deploy the federated learning technique. 1) The collected non-IID data across the network (i.e., the data is generated by distinct distributions across different devices), imposes significant statistical challenges to fit a mode from the non-IID data [11], [15]. 2) Large communication loads across mobile devices limit the scalability for federated learning to efficiently exchange locally computed updates at each device [10], [16]. 3) The heterogeneity of computation, storage and communication capabilities across different devices brings unique system challenges to tame latency for on-device distributed training, e.g., the stragglers (i.e., devices that run slow) may cause significant delays [8], [17]. 4) The arbitrarily adversarial behaviors of the devices (e.g., Byzantine failures [18]) bring critical security issues for large-scale distributed learning, which will incur a major degradation of the learning performance [19]. 5) System implementation issues such as the unreliable device connectivity, interrupted execution and slow convergence compared with learning on centralized data [12]. In particular, the federated averaging (FedAvg) algorithm [10] turns out to be a promising way to efficiently average the locally updated model at each device with unbalanced and non-IID data, thereby reducing the number of communication rounds between the center node and the end devices.

In this paper, we focus on designing the fast model aggregation approach for the FedAvg algorithm to improve the communication efficiency and speed up the federated learning system. We observe that the global model aggregation procedure consists of the transmission of locally computed updates from each device, followed by the computation of their weighted average at a central node. We shall propose

a computation and communication co-design approach for fast model aggregation by leveraging the principles of overthe-air computation (AirComp) [20]. This is achieved by exploring the superposition property of a wireless multipleaccess channel to compute the desired function (i.e., the weighted average function) of distributed locally computed updates via concurrent transmission. Although the AirComp problem has achieved significant progresses from the point of view of information theory [20], signal processing [21] and transceiver beamforming design [22], the AirComp based model aggregation problem brings unique challenges as we need to simultaneously minimize the function distortion and maximize the number of involved devices. This is based on the key observations that the aggregation errors may lead to a notable drop of the prediction accuracy, while the convergence of training can be accelerated with more involved devices [10], [23]. To improve the communication efficiency and statistical performance of federated learning, we shall propose a joint device selection and receiver beamforming design approach to find the maximum selected devices with the mean-square-error (MSE) requirement for fast model aggregation via AirComp. Note that the tradeoff of learning performance and aggregation error is also considered in the recent parallel work [24], which quatifies the device population of the truncation-based approach for excluding the devices with deep fading channel.

However, the joint device selection and beamforming design problem is essentially a computationally difficult mixed combinatorial optimization problem with nonconvex quadratic constraints. Specifically, device selection needs to maximize a combinatorial objective function, while the MSE requirement yields nonconvex quadratic constraints due to the multicasting duality for receiver beamforming design in AirComp [22]. To address the computational issue, we propose a sparse and lowrank modeling approach to assist efficient algorithms design. This is achieved by finding a sparse representation for the combinatorial objective function, followed by reformulating the nonconvex quadratic constraints as affine constraints with an additional rank-one matrix constraint by adopting the matrix lifting technique [25]. For the sparse optimization problem, ℓ_1 -norm is a celebrated convex surrogate for the nonconvex ℓ_0 -norm. The nonconvex smoothed ℓ_p -norm supported by the iteratively reweighted algorithm is a promising way to enhance the sparsity level [26], [27]. However, its convergence results rely on the carefully chosen smoothing parameter. Although the semidefinite relaxation (SDR) technique convexifies the nonconvex quadratic constraints as a linear constraint via dropping the rank-one constraint in the lifting problem, the performance degenerates with large number of antennas as its weak capability of inducing low-rank structures [28].

To address the limitations of existing algorithms for solving the presented sparse and low-rank optimization problem, we propose a unified difference-of-convex-functions (DC) approach to induce both the sparsity and low-rank structures. Specifically, to enhance sparsity, we adopt a novel DC representation for the ℓ_0 -norm [29], which is given by the difference of the ℓ_1 -norm and the Ky Fan k-norm [30], i.e., sum of the largest k absolute values. We also provide a DC representation for the rank-one constraint of the positive semidefinite matrix

by setting the difference between its trace norm and spectral norm as zero. Based on the novel DC representations for the sparse function and low-rank constraint, we propose to induce the sparse structure in the first step as a guideline for the priority of selecting devices. In the second step, we solve a number of feasibility detection problems to find the maximum selected devices via accurately satisfying the rank-one constraint. Our proposed DC approach for enhancing sparsity is parameter free. The exact detection of the rank-one constraint is critical for accurately detecting the feasibility of nonconvex quadratic constraints in the procedure of device selection. Furthermore, the computationally efficient DC Algorithm (DC) with global convergence guarantee is developed by successively solving the convex relaxation of primal problem and dual problem of the DC program. These algorithmic advantages make the proposed DC approach for sparse and low-rank optimization outperform state-of-the-art approaches considerably.

A. Contributions

In this paper, we propose a novel over-the-air computation approach to enable fast global model aggregation for on-device distributed federated learning via harnessing the signal superposition property of a wireless multiple-access channel. To improve the statistical learning performance and the convergence rate for on-device distributed learning, we propose to maximize the number of involved devices for global model aggregation while satisfying the MSE requirement to reduce the model aggregation error. This is achieved by joint device selection and beamforming design, which is further modeled as a sparse and low-rank optimization problem. A novel DC approach is developed to enhance sparsity and accurately detect rank-one constraint. The DC algorithm with established convergence rate is further developed via successively convex relaxation.

The main contributions of the paper are summarized as follows:

- We design a novel fast model aggregation approach for federated learning via exploiting signal superposition property of a wireless multiple-access channel using the principles of over-the-air computation. This idea is achieved by joint device selection and beamforming design to improve the statistical learning performance.
- 2) A sparse and low-rank modeling approach is provided to support efficient algorithms design for the joint device selection and beamforming problem, which is essentially a highly intractable combinatorial optimization problem with nonconvex quadratic constraints.
- 3) To address the limitations of existing algorithms for sparse and low-rank optimization, we propose a unified DC representation approach to induce both the sparse and low-rank structures. The proposed DC approach has the capability of accurately detecting the feasibility of nonconvex quadratic constraints, which is critical in the procedure of device selection.
- 4) We further develop a DC algorithm for the presented nonconvex DC program via successive convex relaxation. The global convergence rate of the DC algorithm is

further established by rewriting the DC function as the difference of strongly convex functions.

The superiority of the proposed DC approach for accurately feasibility detection and device selection will be demonstrated through extensive numerical results. It turns out that our proposed approaches can achieve better prediction accuracy and faster convergence rate in the experiments of training support vector machine (SVM) classifier on CIFAR-10 dataset.

B. Organization

The remaining part of this work is organized as follows. Section II introduces the system model of on-device distributed federated learning and problem formulation for fast model aggregation. Section III presents a sparse and low-rank modeling approach for model aggregation. Section IV provides the DC representation framework for solving the sparse and low-rank optimization problem, while in Section V the DC Algorithm is developed and its convergence rate is also established. The performances of the proposed approaches and other state-of-the-art approaches are illustrated in Section VI. We conclude this work in Section VII.

II. SYSTEM MODEL AND PROBLEM FORMULATION

In this section, the on-device distributed federated learning system is presented. Based on the principles of over-the-air computation, we propose a computation and communication co-design approach based on the principles of over-the-air computation for fast model aggregation of locally computed updates at each device to improve the global model.

A. On-Device Distributed Federated Learning

As an on-device distributed training system, federated learning keeps the training data at each device and learns a shared global model from distributed mobile devices. With this novel distributed learning paradigm, lots of benefits can be harnessed such as low-latency, low power consumption as well as preserving users' privacy [10]. Fig. 1 illustrates the federated learning system with M single-antenna mobile devices and one computing enabled base station (BS) equipped with N antennas to support the following distributed machine learning task:

$$\underset{\boldsymbol{z} \in \mathbb{R}^d}{\text{minimize}} \quad f(\boldsymbol{z}) = \frac{1}{T} \sum_{i=1}^T f_i(\boldsymbol{z}), \tag{1}$$

where z is the model parameter vector to be optimized with dimension d and T is the total number of data points. This model is widely used in linear regression, logistic regression, support vector machine, as well as deep neural networks. Typically, each function f_i is parameterized by $\ell(z; x_i, y_i)$, where ℓ is a loss function with the input-output data pair as (x_i, y_i) . Here, $\mathcal{D} = \{(x_i, y_i) : i = 1, \cdots, T\}$ denotes the dataset involved in the training process. The local dataset at device k is denoted as $\mathcal{D}_k \subseteq \mathcal{D}$.

A recognized problem for on-device distributed federated learning system is the limited network bandwidth, which becomes the main bottleneck for globally aggregating the

Fig. 1: On-device distributed federated learning system.

locally computed updates at each mobile device. To reduce the number of communication rounds between mobile devices and the BS for global model updating, the federated averaging (FedAvg) algorithm [10] has recently been proposed, which is also referred to as model averaging. Specifically, at the t-th round:

- 1) The BS selects a subset of mobile devices $S_t \subseteq \{1, \dots, M\}$;
- 2) The BS sends the updated global model $z^{[t-1]}$ to the selected devices S_t ;
- 3) Each selected device $k \in \mathcal{S}_t$ runs a local update algorithm (e.g., stochastic gradient algorithm) based on its local dataset \mathcal{D}_k and the global model $\boldsymbol{z}^{[t-1]}$, whose output is the updated local model $\boldsymbol{z}_k^{[t]}$;
- 4) The BS aggregates all the local updates $z_k^{[t]}$ with $k \in \mathcal{S}_t$, i.e., computing their weighted average as the updated global model $z^{[t]}$.

The federated averaging framework is thus presented in Algorithm 1.

Algorithm 1: Federated Averaging (FedAvg) Algorithm

In this paper, we aim at improving the communication efficiency for on-device distributed federated learning by developing a fast model aggregation approach for locally computed updates in the FedAvg algorithm. A key observation for the FedAvg algorithm is that the statistical learning performance can be improved by selecting more workers in each round [10], [23]. As an illustrative example in Fig. 2, we train an support vector machine (SVM) classifier on the CIFAR-10

dataset [31] with FedAvg algorithm and show the training loss and prediction accuracy over the number of selected devices. The federated learning system consists of 10 mobile devices in total and the selected devices are chosen uniformly at random for each round. However, selecting more devices also brings higher communication overhead for aggregating the local computed updates at each selected device.

Fig. 2: The training loss and prediction accuracy with different number of randomly selected devices for FedAvg. We train an support vector machine (SVM) classifier on the CIFAR-10 dataset and adopt the stochastic gradient descent algorithm [31] as the local update algorithm for each device. Each curve is averaged for 10 times. The relative prediction accuracy is defined as the accuracy over random classification.

Note that the model aggregation procedure requires the computation of the weighted average of locally computed updates and the communication from selected mobile devices to the BS. Therefore, in this paper we develop a novel communication and computation co-design approach for fast model aggregation. Our approach is based on the principles of *over-the-air computation* [20] by leveraging the signal superposition property of a multiple-access channel. Furthermore, we notice that the aggregation error also causes a notable drop of the prediction accuracy [32]. To address this issue, we shall develop efficient transceiver strategies to minimize the distortion error for model aggregation via over-the-air

computation. Based on the above key observations, in this paper, we focus on the following two aspects to improve the statistical learning performance in on-device distributed federated learning system:

- Maximize the number of selected devices at each round to improve the convergence rate in the distributed training process;
- Minimize the model aggregation error to improve the prediction accuracy in the inference process.

B. Over-the-Air Computation for Aggregation

Over-the-air computation has become a promising approach for fast wireless data aggregation via computing a nomographic function (e.g., arithmetic mean) of distributed data from multiple transmitters [21]. By integrating computation and communication through exploiting the signal superposition property of a multiple-access channel, over-the-air computation can accomplish the computation of target function via concurrent transmission, thereby significantly improving the communication efficiency compared with orthogonal transmission. The key observation in the FedAvg algorithm is that the global model is updated through computing the weighted average of locally computed updates at each selected device, which falls in the category of computing nomographic functions of distributed data. In this paper, we shall propose the over-the-air computation approach for communication efficient aggregation in federated learning system.

Specifically, the target vector for aggregating local updates in the FedAvg algorithm is given by

$$z = \psi \left(\sum_{i \in \mathcal{S}} \phi_i(z_i) \right), \tag{2}$$

where z_i is the updated local model at the i-th device, $\phi_i = |\mathcal{D}_i|$ is the pre-processing scalar at device $i, \psi = \frac{1}{\sum_{k \in \mathcal{S}} |\mathcal{D}_k|}$ is the post-processing scalar at the BS, and \mathcal{S} is the selected set of mobile devices. The symbol vector for each local model before pre-processing $s_i := z_i \in \mathbb{C}^d$ is assumed to be normalized with unit variance, i.e., $\mathbb{E}(s_i s_i^{\mathsf{H}}) = I$. At each time slot $j \in \{1, \cdots, d\}$, each device sends the signal $s_i^{(j)} \in \mathbb{C}$ to the BS. We denote

$$g^{(j)} = \sum_{i \in \mathcal{S}} \phi_i \left(s_i^{(j)} \right) \tag{3}$$

as the target function to be estimated through over-the-air computation at the j-th time slot.

To simplify the notation, we omit the time index by writing $g^{(j)}$ and $s_i^{(j)}$ as g and s_i , respectively. The received signal at the BS is given by

$$y = \sum_{i \in \mathcal{S}} h_i b_i s_i + n, \tag{4}$$

where $b_i \in \mathbb{C}$ is the transmitter scalar, $h_i \in \mathbb{C}^N$ is the channel vector between device i and the BS, and $n \sim \mathcal{CN}(\mathbf{0}, \sigma^2 \mathbf{I})$ is the noise vector. The transmit power constraint at device i is given by

$$\mathbb{E}(|b_i s_i|^2) = |b_i|^2 \le P_0 \tag{5}$$

with $P_0 > 0$ as the maximum transmit power. The estimated value before post-processing at the BS is given as

$$\hat{g} = \frac{1}{\sqrt{\eta}} \mathbf{m}^{\mathsf{H}} \mathbf{y} = \frac{1}{\sqrt{\eta}} \mathbf{m}^{\mathsf{H}} \sum_{i \in \mathcal{S}} \mathbf{h}_i b_i s_i + \frac{\mathbf{m}^{\mathsf{H}} \mathbf{n}}{\sqrt{\eta}}, \tag{6}$$

where $m \in \mathbb{C}^N$ is the receiver beamforming vector and η is a normalizing factor. Each element of the target vector can thus be obtained as $\hat{z} = \psi(\hat{g})$ at the BS.

The distortion of \hat{g} with respect to the target value g given in equation (3), which quantifies the over-the-air computation performance for global model aggregation in the FedAvg algorithm, is measured by the mean-squared-error (MSE) defined as

$$\mathsf{MSE}(\hat{g}, g) = \mathbb{E}\left(|\hat{g} - g|^2\right)$$

$$= \sum_{i \in S} \left| \mathbf{m}^{\mathsf{H}} \mathbf{h}_i b_i / \sqrt{\eta} - \phi_i \right|^2 + \sigma^2 \|\mathbf{m}\|^2 / \eta. \tag{7}$$

Motivated by [28], we have the following proposition for transmitter beamformers:

Proposition 1. Given a receiver beamforming vector m, the MSE is minimized by the following zero-forcing transmitter:

$$b_i = \sqrt{\eta} \phi_i \frac{(\boldsymbol{m}^{\mathsf{H}} \boldsymbol{h}_i)^{\mathsf{H}}}{\|\boldsymbol{m}^{\mathsf{H}} \boldsymbol{h}_i\|^2}.$$
 (8)

Proof. See Appendix A.

Due to the transmit power constraint (5) for transmit scalar b_i given in (8), we have

$$\eta = \min_{i \in \mathcal{S}} \frac{P_0 \|\boldsymbol{m}^{\mathsf{H}} \boldsymbol{h}_i\|^2}{\phi_i^2}.$$
 (9)

The MSE is thus given as

$$\mathsf{MSE}(\hat{g}, g; \mathcal{S}, \boldsymbol{m}) = \frac{\|\boldsymbol{m}\|^2 \sigma^2}{\eta} = \frac{\sigma^2}{P_0} \max_{i \in \mathcal{S}} \phi_i^2 \frac{\|\boldsymbol{m}\|^2}{\|\boldsymbol{m}^\mathsf{H} \boldsymbol{h}_i\|^2}.(10)$$

C. Problem Formulation

As discussed in Section II-A, the number of selected devices shall be maximized to improve the learning performance for distributed federated learning. In addition, the aggregation error through over-the-air computation is supposed to be reduced to avoid the notable drop of model prediction accuracy. In this paper, we propose to find the maximum selected devices while guaranteeing the MSE requirement for over-the-air computation. It is formulated as the following mixed combinatorial optimization problem

where $\gamma>0$ is the MSE requirement for model aggregation. However, the mixed combinatorial optimization problem (11) is highly intractable due to the combinatorial objective function $|\mathcal{S}|$ and the nonconvex MSE constraint with coupled combinatorial variable \mathcal{S} and continuous variable m. To address the nonconvexity of MSE function, [28] finds the

connections between the nonconvex MSE constraint (11) and the nonconvex quadratic constraints for efficient algorithm designing. Enlightened by this observation, we will show that problem (11) can be equivalently solved by maximizing the number of feasible nonconvex quadratic constraints. Specifically, to support efficient algorithms design, we shall propose a sparse representation approach to find the maximum number of involved devices, followed by reformulating the nonconvex quadratic constraints as affine constraints with an additional rank-one constraint by the matrix lifting technique.

III. SPARSE AND LOW-RANK OPTIMIZATION FOR ON-DEVICE DISTRIBUTED FEDERATED LEARNING

In this section, we propose a sparse and low-rank optimization modeling approach for on-device distributed federated learning with device selection.

A. Sparse and Low-Rank Optimization

To support efficient algorithms design, we first rewrite problem (11) as the mixed combinatorial optimization problem with nonconvex quadratic constraints as presented in Proposition 2.

Proposition 2. Problem (11) is equivalent to the following mixed combinatorial optimization problem:

where $\gamma_i = \gamma/\phi_i^2$. That is, our target becomes maximizing the number of feasible MSE constraints $\|\boldsymbol{m}\|^2 - \gamma_i \|\boldsymbol{m}^{\mathsf{H}} \boldsymbol{h}_i\|^2 \leq 0$ under the regularity condition $\|\boldsymbol{m}\|^2 \geq 1$.

Proof. Problem (11) can be reformulated as

maximize
$$|\mathcal{S}|$$

subject to $F_i(\boldsymbol{m}) = \|\boldsymbol{m}\|^2 - \gamma_i \|\boldsymbol{m}^\mathsf{H} \boldsymbol{h}_i\|^2 \le 0, i \in \mathcal{S}$
 $\boldsymbol{m} \ne \boldsymbol{0}.$ (13)

which is further equivalently rewritten as

maximize
$$|\mathcal{S}|$$

subject to $F_i(\boldsymbol{m})/\tau = \|\boldsymbol{m}\|^2/\tau - \gamma_i \|\boldsymbol{m}^\mathsf{H} \boldsymbol{h}_i\|^2/\tau \le 0, i \in \mathcal{S}$
 $\|\boldsymbol{m}\|^2 \ge \tau, \tau > 0.$ (14)

Then by introducing variable $\tilde{m} = m/\sqrt{\tau}$, problem (14) can be reformulated as

maximize
$$|\mathcal{S}|$$

subject to $F_i(\tilde{\boldsymbol{m}}) = \|\tilde{\boldsymbol{m}}\|^2 - \gamma_i \|\tilde{\boldsymbol{m}}^\mathsf{H} \boldsymbol{h}_i\|^2 \le 0, \quad i \in \mathcal{S},$
 $\|\tilde{\boldsymbol{m}}\|^2 \ge 1.$ (15)

Therefore, problem (11) is equivalent to problem (12), where the regularity condition $\|\boldsymbol{m}\|^2 \geq 1$ serves the purpose of avoiding the singularity (i.e., $\boldsymbol{m}=0$).

To maximize the number of feasible MSE constraints in problem (12), we can minimize the number of nonzero x_k 's [26], i.e.,

$$\begin{aligned} & \underset{\boldsymbol{x} \in \mathbb{R}_{+}^{M}, \boldsymbol{m} \in \mathbb{C}^{N}}{\text{minimize}} & & \|\boldsymbol{x}\|_{0} \\ & \text{subject to} & & \|\boldsymbol{m}\|^{2} - \gamma_{i} \|\boldsymbol{m}^{\mathsf{H}} \boldsymbol{h}_{i}\|^{2} \leq x_{i}, \forall i, \\ & & & \|\boldsymbol{m}\|^{2} \geq 1. \end{aligned}$$
 (16)

The sparsity structure of x indicates the feasibility of each mobile device. If $x_i = 0$, the *i*-th mobile device can be selected while satisfying the MSE requirement.

However, both the MSE constraints and the regularity condition in problem (16) are nonconvex quadratic constraints. To addressed this nonconvexity issue, a natural way is adopting the matrix lifting technique [33]. Specifically, by lifting vector m as the positive semidefinite (PSD) matrix $M = mm^{\rm H}$ with ${\rm rank}(M) = 1$, problem (16) can be reformulated as the following sparse and low-rank optimization problem

$$\mathcal{P}: \underset{\boldsymbol{x} \in \mathbb{R}_{+}^{M}, \boldsymbol{M} \in \mathbb{C}^{N \times N}}{\text{minimize}} \quad \|\boldsymbol{x}\|_{0} \\
\text{subject to} \quad \operatorname{Tr}(\boldsymbol{M}) - \gamma_{i} \boldsymbol{h}_{i}^{\mathsf{H}} \boldsymbol{M} \boldsymbol{h}_{i} \leq x_{i}, \forall i, \\
\boldsymbol{M} \succeq \boldsymbol{0}, \operatorname{Tr}(\boldsymbol{M}) \geq 1, \\
\operatorname{rank}(\boldsymbol{M}) = 1. \tag{17}$$

Although problem \mathcal{P} is still nonconvex, we shall demonstrate its algorithmic advantages by developing efficient algorithms.

B. Problem Analysis

Problem \mathscr{P} is a nonconvex optimization problem with sparse objective function and low-rank constraint. Sparse optimization and low-rank optimization have attracted much attention in machine learning, signal processing, high-dimensional statistics, as well as wireless communication [34], [35], [36], [37], [38]. Although the sparse function and the low rank function are both nonconvex and computationally difficult, significant progress has been achieved for taming the nonconvexity via developing efficient and provable algorithms by exploiting various problem structures.

- 1) Sparse Optimization: ℓ_1 -norm is a natural convex surrogate for the nonconvex sparse function, i.e., ℓ_0 -norm. The resulting problem is known as the sum-of-infeasibilities in the literature of optimization [39]. Another known approach for enhancing sparsity is the smoothed ℓ_p -minimization [26] by finding a tight approximation for the nonconvex ℓ_0 -norm, followed by the iteratively reweighted ℓ_2 -minimization algorithm. However, the smoothing parameters should be chosen carefully since the convergence behavior of iterative reweighted algorithms may be sensitive to them [40], [27].
- 2) Low-Rank Optimization: Simply dropping the rank-one constraint in problem \mathscr{P} yields the semidefinite relaxation (SDR) technique [25]. The SDR technique is widely used as an effective approach to find approximate solutions for the nonconvex quadratic constrained quadratic programs. If the solution fails to be rank-one, we can obtain a rank-one approximate solution through the Gaussian randomization method [25]. However, when the number of antennas N

increases, its performance deteriorates since the probability of returning rank-one solutions is low [28], [41].

To address the limitations of the existing works, in this paper, we shall propose a unified difference-of-convex-functions (DC) programming approach to solve the sparse and low-rank optimization problem \mathscr{P} . This approach is able to enhance the sparsity in the objective as well as accurately detect the infeasibility in the nonconvex quadratic constraints, yielding considerably improvements compared with state-of-the-art algorithms. Specifically,

- We will develop a parameter-free DC approach to enhance sparsity, thereby maximizing the number of selected devices.
- Instead of dropping the rank-one constraint directly, we will propose a novel DC approach to guarantee the exact rank-one constraint.

Note that the proposed DC approach has the capability of guarantee the feasibility of rank-one constraint, which is critical for accurately detecting the feasibility of the nonconvex quadratic constraints in the procedure of device selection.

IV. DC REPRESENTATION FOR THE SPARSE AND LOW-RANK FUNCTIONS

In this section, we shall propose a unified DC representation framework to solve the sparse and low-rank optimization problem \mathscr{P} for federated learning with device selection. Specifically, the sparsity is induced by a novel DC representation for the ℓ_0 -norm. The sparsity structure provides a guideline for device selection. We then solve a sequence of feasibility detection problems with nonconvex quadratic constraints to find maximum selected devices. In particular, we present a novel DC representation for the rank function in the lifting problem to satisfy the rank-one constraint, which is capable of accurately detecting the feasibility of nonconvex quadratic programs during device selection procedure.

A. DC Representation for Sparse Function

Before introducing the DC representation for the ℓ_0 -norm, we first give the definition of Ky Fan k-norm.

Definition 1. Ky Fan k-norm [30]: The Ky Fan k-norm of vector $\mathbf{x} \in \mathbb{C}^M$ is a convex function of \mathbf{x} and is given by the sum of largest-k absolute values, i.e.,

$$|||x|||_k = \sum_{i=1}^M |x_{\pi(i)}|, \tag{18}$$

where π is a permutation of $\{1, \cdots, M\}$ and $|x_{\pi(1)}| \ge \cdots \ge |x_{\pi(M)}|$.

If the ℓ_0 -norm is less than k, its ℓ_1 -norm is equal to its Ky Fan k-norm. Based on this fact, the ℓ_0 -norm can be represented by the difference between ℓ_1 -norm and Ky Fan k-norm [29]:

$$\|\boldsymbol{x}\|_{0} = \min\{k : \|\boldsymbol{x}\|_{1} - \|\boldsymbol{x}\|_{k} = 0, 0 \le k \le M\}.$$
 (19)

B. DC Representation for Low-Rank Constraint

For the positive semidefinite (PSD) matrix $M \in \mathbb{C}^{N \times N}$, the rank-one constraint can be equivalently rewritten as

$$\sigma_i(\mathbf{M}) = 0, \forall i = 2, \cdots, N,$$
 (20)

where $\sigma_i(M)$ is the *i*-th largest singular value of matrix M. Note that the trace norm and spectral norm are given by

$$\operatorname{Tr}(\boldsymbol{M}) = \sum_{i=1}^{N} \sigma_i(\boldsymbol{M}) \text{ and } \|\boldsymbol{M}\|_2 = \sigma_1(\boldsymbol{M}), \quad (21)$$

respectively. Therefore, we have the following proposition:

Proposition 3. For PSD matrix M and $Tr(M) \ge 1$, we have

$$\operatorname{rank}(\boldsymbol{M}) = 1 \Leftrightarrow \operatorname{Tr}(\boldsymbol{M}) - \|\boldsymbol{M}\|_2 = 0. \tag{22}$$

Proof. If the rank of PSD matrix M is one, the trace norm is equal to the spectral norm as $\sigma_i(M) = 0$ for all $i \geq 2$. The equation $\text{Tr}(M) - \|M\|_2 = 0$ implies that $\sigma_i(M) = 0$ for all $i \geq 2$, i.e., $\text{rank}(M) \leq 1$. And we have $\sigma_1(M) > 0$ from $\text{Tr}(M) \geq 1$. Therefore, rank(M) = 1 holds if $\text{Tr}(M) - \|M\|_2 = 0$.

C. A Unified DC Representation Framework

The main idea of our proposed DC representation framework is to induce the sparsity of \boldsymbol{x} in the first step, which will provide guidelines for determining the priority of selecting devices. Then we shall solve a series of feasibility detection problems to find maximum selected devices such that the MSE requirement is satisfied. This two-step framework is illustrated in Fig. 3. And each step will be accomplished by solving a DC program.

Fig. 3: A two-step framework for device selection.

1) Step 1: Sparsity Inducing: In the first step, we solve the following DC program for problem \mathcal{P} :

$$\begin{split} \mathscr{P}_{\mathrm{S1}} : & \underset{\boldsymbol{x},\boldsymbol{M}}{\text{minimize}} & \|\boldsymbol{x}\|_1 - \|\boldsymbol{x}\|_k + \mathrm{Tr}(\boldsymbol{M}) - \|\boldsymbol{M}\|_2 \\ & \text{subject to} & \mathrm{Tr}(\boldsymbol{M}) - \gamma_i \boldsymbol{h}_i^\mathsf{H} \boldsymbol{M} \boldsymbol{h}_i \leq x_i, \forall i = 1, \cdots, M \\ & \boldsymbol{M} \succeq \boldsymbol{0}, & \mathrm{Tr}(\boldsymbol{M}) \geq 1, \boldsymbol{x} \succeq \boldsymbol{0}. \end{split} \tag{23}$$

By sequentially solving problem \mathscr{P}_{S1} , we can obtain the sparse vector \boldsymbol{x}^{\star} such that the objective value achieves zero through increasing k from 0 to M. Note that the rank one constraint of matrix \boldsymbol{M} shall be satisfied when the objective value equals zero with $\text{Tr}(\boldsymbol{M}) - \|\boldsymbol{M}\|_2 = 0$.

2) Step II: Feasibility Detection: The solution x obtained in the first step characterizes the gap between the MSE requirement and the achievable MSE for each device. Therefore, in the second step, we propose to select device k with higher priority if x_k is small. The elements of x can be arranged in descending order $x_{\pi(1)} \ge \cdots \ge x_{\pi(M)}$. We will find the minimum k by increasing k from 1 to M such that selecting

all devices in $\mathcal{S}^{[k]}$ is feasible, where the set $\mathcal{S}^{[k]}$ is chosen as $\{\pi(k), \pi(k+1), \cdots, \pi(M)\}.$

In detail, if all devices in $S^{[k]}$ can be selected, the following optimization problem

find
$$\boldsymbol{m}$$
 subject to $\|\boldsymbol{m}\|^2 - \gamma_i \|\boldsymbol{m}^{\mathsf{H}} \boldsymbol{h}_i\|^2 \le 0, \forall i \in \mathcal{S}^{[k]}$ $\|\boldsymbol{m}\|^2 \ge 1.$ (24)

should be feasible. It can be equivalently reformulated as

find
$$M$$

subject to $\operatorname{Tr}(M) - \gamma_i h_i^{\mathsf{H}} M h_i \leq 0, \forall i \in \mathcal{S}^{[k]}$
 $M \succeq \mathbf{0}, \operatorname{Tr}(M) \geq 1, \operatorname{rank}(M) = 1$ (25)

using the matrix lifting technique. To guarantee the feasibility of the fixed-rank constraint for accurately detecting the feasibility of MSE constraints, we propose the following DC approach by minimizing the difference between trace norm and spectral norm:

$$\begin{split} \mathscr{P}_{\text{S2}} : & \underset{\boldsymbol{M}}{\text{minimize}} & \operatorname{Tr}(\boldsymbol{M}) - \|\boldsymbol{M}\|_2 \\ & \text{subject to} & \operatorname{Tr}(\boldsymbol{M}) - \gamma_i \boldsymbol{h}_i^{\mathsf{H}} \boldsymbol{M} \boldsymbol{h}_i \leq 0, \forall i \in \mathcal{S}^{[k]} \\ & \boldsymbol{M} \succeq \boldsymbol{0}, & \operatorname{Tr}(\boldsymbol{M}) \geq 1. \end{split} \tag{26}$$

That is, when the objective value of problem \mathscr{P}_{S2} equals zero given set $\mathcal{S}^{[k]}$, we conclude that all devices in $\mathcal{S}^{[k]}$ are selected while satisfying the MSE requirement, i.e., problem (24) is feasible for $\mathcal{S}^{[k]}$. Note that the solution M^* shall be an exact rank-one matrix and a feasible receiver beamforming vector m can be obtained through Cholesky decomposition $M^* = mm^H$.

The proposed DC representation framework for solving the sparse and low-rank optimization problem in federated learning is presented in Algorithm 2. Since the DC program is still nonconvex, in next section, we will develop the DC Algorithm (DC) [42] for the DC optimization problem \mathcal{P}_{S1} and problem \mathcal{P}_{S2} . We further contribute by establishing the convergence rate of DC algorithm. Due to the superiority of the presented DC representation (22) for rank-one constraint, our proposed DC approach for accurate feasibility detection considerably outperforms the SDR approach [25] by simply dropping the rank-one constraint, which will be demonstrated through numerical experiments in Section V.

V. DC ALGORITHM FOR DC PROGRAM WITH CONVERGENCE GUARANTEES

In this section, the DC Algorithm will be developed by successively solving the convex relaxation of primal problem and dual problem of DC program. To further establish the convergence results, we add quadratic terms in convex functions while their difference (i.e., the objective value) remains unchanged. With this technique, we represent the DC objective function as the difference of strongly convex functions, which allows us establish the convergence rate of the DC algorithm.

Algorithm 2: DC Representation Framework for Solving Problem \mathscr{P} in Federated Learning with Device Selection

 $\begin{array}{l} \textbf{Step 1:} \text{ sparsity inducing} \\ k \leftarrow 0 \\ \textbf{while } objective \ value \ of \ \mathscr{P}_{S1} \ is \ not \ zero \ \textbf{do} \\ \hline \text{Obtain solution } \textbf{\textit{x}} \ \text{by solving the DC program} \\ \hline \mathscr{P}_{S1} \\ k \leftarrow k+1 \\ \textbf{end} \end{array}$

Step 2: feasibility detection

Order \boldsymbol{x} in descending order as $x_{\pi(1)} \geq \cdots \geq x_{\pi(M)}$ $k \leftarrow 1$

Output: m through Cholesky decomposition $M = mm^{\mathsf{H}}$, and the set of selected devices $\mathcal{S}^{[k]} = \{\pi(k), \pi(k+1), \cdots, \pi(M)\}$

A. Difference-of-Strongly-Convex-Functions Representation

The DC formulations \mathcal{P}_{S1} and \mathcal{P}_{S2} for sparse and lowrank optimization are nonconvex programs with DC objective functions and convex constraints. Although DC functions are nonconvex, they have good problem structures and the DC Algorithm can be developed based on the principles provided in [42]. In order to establish the convergence result of the DC algorithm, we will represent the DC objective function as the difference of strongly convex functions.

Specifically, we can equivalently rewrite problem \mathscr{P}_{S1} as

minimize
$$f_1 = \|x\|_1 - \|x\|_k + \text{Tr}(M) - \|M\|_2 + I_{C_1}(x, M),$$
(27)

and problem \mathcal{P}_{S2} as

$$\underset{\boldsymbol{M}}{\text{minimize}} f_2 = \text{Tr}(\boldsymbol{M}) - \|\boldsymbol{M}\|_2 + I_{\mathcal{C}_2}(\boldsymbol{M}), \quad (28)$$

respectively. Here C_1 , C_2 are positive semidefinite cones that integrates the constraints of problem \mathcal{P}_{S1} and problem \mathcal{P}_{S2} , and the indicator function is defined as

$$I_{\mathcal{C}_1}(\boldsymbol{x}, \boldsymbol{M}) = \begin{cases} 0, & (\boldsymbol{x}, \boldsymbol{M}) \in \mathcal{C}_1 \\ +\infty, & \text{otherwise} \end{cases}$$
 (29)

In order to establish the convergence result of the DC algorithm, we rewrite the DC functions f_1 , f_2 as the difference of *strongly* convex functions, i.e., $f_1 = g_1 - h_1$ and $f_2 = g_2 - h_2$,

where

$$g_1 = \|\mathbf{x}\|_1 + \text{Tr}(\mathbf{M}) + I_{\mathcal{C}_1}(\mathbf{x}, \mathbf{M}) + \frac{\alpha}{2}(\|\mathbf{x}\|_F^2 + \|\mathbf{M}\|_F^2),$$
(30)

$$h_1 = \|\mathbf{x}\|_k + \|\mathbf{M}\|_2 + \frac{\alpha}{2}(\|\mathbf{x}\|_F^2 + \|\mathbf{M}\|_F^2),$$
 (31)

$$g_2 = \text{Tr}(\mathbf{M}) + I_{\mathcal{C}_2}(\mathbf{M}) + \frac{\alpha}{2} ||\mathbf{M}||_F^2,$$
 (32)

$$h_2 = \|\mathbf{M}\|_2 + \frac{\alpha}{2} \|\mathbf{M}\|_F^2. \tag{33}$$

By adding quadratic terms, g_1, g_2, h_1, h_2 are all α -strongly convex functions. Then problem (27) and problem (28) admit the uniform structure of minimizing the difference of two strongly convex functions

$$\underset{\mathbf{X} \in \mathbb{C}^{m \times n}}{\text{minimize}} \quad f(\mathbf{X}) = g(\mathbf{X}) - h(\mathbf{X}). \tag{34}$$

For complex domain X, we shall apply Wirtinger calculus [43] for algorithm design. The DC algorithm is given by constructing sequences of candidates to primal solutions and dual solutions. Since the primal problem (34) and its dual problem are still nonconvex, convex relaxation is further needed.

B. DC Algorithm for Sparse and Low-Rank Optimization

According to the Fenchel's duality [44], the dual problem of problem (34) is given by

$$\underset{\mathbf{Y} \in \mathbb{C}^{m \times n}}{\text{minimize}} \quad h^*(\mathbf{Y}) - g^*(\mathbf{Y}), \tag{35}$$

where g^* and h^* are the conjugate functions of g and h, respectively. The conjugate function is defined as

$$g^{*}(\boldsymbol{Y}) = \sup_{\boldsymbol{X} \in \mathbb{C}^{m \times n}} \langle \boldsymbol{X}, \boldsymbol{Y} \rangle - g(\boldsymbol{X}), \tag{36}$$

where $\langle \boldsymbol{X}, \boldsymbol{Y} \rangle = \text{Real} \big(\text{Tr}(\mathbf{X}^H \mathbf{Y}) \big)$ defines the inner product of two matrices [43]. The *t*-th iteration of the simplified DC algorithm is to solve the convex approximation of primal problem and dual problem by linearizing the concave part:

$$\boldsymbol{Y}^{[t]} = \arg\inf_{\boldsymbol{Y} \in \mathcal{Y}} h^*(\boldsymbol{Y}) - [g^*(\boldsymbol{Y}^{[t-1]}) + \langle \boldsymbol{Y} - \boldsymbol{Y}^{[t-1]}, \boldsymbol{X}^{[t]} \rangle],$$
(37)

$$\boldsymbol{X}^{[t+1]} = \arg \inf_{\boldsymbol{X} \in \mathcal{X}} \ g(\boldsymbol{X}) - [h(\boldsymbol{X}^{[t]}) + \langle \boldsymbol{X} - \boldsymbol{X}^{[t]}, \boldsymbol{Y}^{[t]} \rangle]. \tag{38}$$

According to the Fenchel biconjugation theorem [44], equation (37) can be rewritten as

$$\boldsymbol{Y}^{[t]} \in \partial_{\boldsymbol{X}^{[t]}} h,\tag{39}$$

 $\partial_{\mathbf{X}^{[t]}} h$ is the subgradient of h with respect to \mathbf{X} at $\mathbf{X}^{[t]}$.

Therefore, iterations $x^{[t]}, M^{[t]}$ of the DC algorithm for problem \mathcal{P}_{S1} are constructed as the solution to the following convex optimization problem

minimize
$$g_1 - \langle \partial_{\boldsymbol{x}^{[t-1]}} h_1, \boldsymbol{x} \rangle - \langle \partial_{\boldsymbol{M}^{[t-1]}} h_1, \boldsymbol{M} \rangle$$

subject to $\operatorname{Tr}(\boldsymbol{M}) - \gamma_i \boldsymbol{h}_i^{\mathsf{H}} \boldsymbol{M} \boldsymbol{h}_i \leq x_i, \forall i = 1, \cdots, M,$
 $\boldsymbol{M} \succeq \boldsymbol{0}, \quad \operatorname{Tr}(\boldsymbol{M}) \geq 1, \boldsymbol{x} \succeq \boldsymbol{0}.$ (40)

The iteration $M^{[t]}$ for problem \mathscr{P}_{S2} is given by the solution to the following optimization problem

The subgradient of h_1 and h_2 are given by

$$\partial_{\boldsymbol{x}} h_1 = \partial \|\boldsymbol{x}\|_k + \alpha \boldsymbol{x},\tag{42}$$

$$\partial_{\mathbf{M}} h_1 = \partial_{\mathbf{M}} h_2 = \partial \|\mathbf{M}\|_2 + \alpha \mathbf{M}. \tag{43}$$

The subgradient of $||x||_k$ can be computed by [29]

$$i\text{-th entry of }\partial \|\mathbf{x}\|_k = \begin{cases} \operatorname{sign}(x_i), & |x_i| \ge |x_{(k)}| \\ 0, & |x_i| < |x_{(k)}| \end{cases}. \tag{44}$$

The subgradient of $\|\mathbf{M}\|_2$ is given by the following proposition.

Proposition 4. The subgradient of $\|M\|_2$ can be computed as $v_1v_1^H$, where $v_1 \in \mathbb{C}^N$ is the eigenvector of the largest eigenvalue $\sigma_1(M)$.

Proof. The subdifferential of orthogonal invariant norm $||M||_2$ for PSD matrix M is given by [45]

$$\partial \|\mathbf{M}\|_{2} = \operatorname{conv}\{V \operatorname{diag}(\mathbf{d})V^{\mathsf{H}} : \mathbf{d} \in \partial \|\boldsymbol{\sigma}(\mathbf{M})\|_{\infty}\}, \quad (45)$$

where conv denotes the convex hull of a set and $M = V \Sigma V^{\mathsf{H}}$ is the singular value decomposition of M, and $\sigma(M) = [\sigma_i(M)] \in \mathbb{C}^N$ is the vector formed by all singular values of M. Since $\sigma_1(M) \geq \cdots \geq \sigma_N(M) \geq 0$, we have

$$[1, \underbrace{0, \cdots, 0}_{N-1}]^{\mathsf{H}} \in \partial \|\boldsymbol{\sigma}(\boldsymbol{M})\|_{\infty}. \tag{46}$$

Therefore, one subgradient of $||M||_2$ is given by $v_1v_1^H$. \square

C. Convergence Analysis

The convergence of the presented DC algorithm for problem \mathcal{P}_{S1} and problem \mathcal{P}_{S2} is given by the following proposition.

Proposition 5. The sequence $\{(M^{[t]}, x^{[t]})\}$ generated by iteratively solving problem (40) for problem \mathcal{P}_{S1} has the following properties:

- (i) The sequence $\{(\boldsymbol{M}^{[t]}, \boldsymbol{x}^{[t]})\}$ converges to a critical point of f_1 (27) from arbitrary initial point, and the sequence of $\{f_1^{[t]}\}$ is strictly decreasing and convergent.
- (ii) For any $t = 0, 1, \dots$, we have

$$\operatorname{Avg}\left(\|\boldsymbol{M}^{[t]} - \boldsymbol{M}^{[t+1]}\|_F^2\right) \le \frac{f_1^{[0]} - f_1^{\star}}{\alpha(t+1)},\tag{47}$$

$$\operatorname{Avg}\left(\|\boldsymbol{x}^{[t]} - \boldsymbol{x}^{[t+1]}\|_{2}^{2}\right) \le \frac{f_{1}^{[0]} - f_{1}^{\star}}{\alpha(t+1)},\tag{48}$$

where f_1^{\star} is the global minimum of f_1 and $\operatorname{Avg}\left(\|\boldsymbol{M}^{[t]} - \boldsymbol{M}^{[t+1]}\|_F^2\right)$ denotes the average of the sequence $\{\|\boldsymbol{M}^{[i]} - \boldsymbol{M}^{[i+1]}\|_F^2\}_{i=0}^t$.

Likewise, the sequence $\{(M^{[t]})\}$ generated by iteratively solving problem (41) for problem \mathcal{P}_{S2} has the following properties:

- (iii) The sequence $\{M^{[t]}\}$ converges to a critical point of f_2 (28) from arbitrary initial point, and the sequence of $\{f_2^{[t]}\}$ is strictly decreasing and convergent.
- (iv) For any $t = 0, 1, \dots$, we have

$$\operatorname{Avg}\left(\|\boldsymbol{M}^{[t]} - \boldsymbol{M}^{[t+1]}\|_F^2\right) \le \frac{f_2^{[0]} - f_2^{\star}}{\alpha(t+1)}.\tag{49}$$

where f_2^{\star} is the global minimum of f_2 .

Proof. Please refer to Appendix B for details.

VI. SIMULATION RESULTS

In this section, we conduct numerical experiments to compare the proposed DC method with state-of-the-art approaches for federated learning with device selection. The channel coefficient vectors \boldsymbol{h}_i 's between the BS and each mobile device follow the i.i.d. complex normal distribution, i.e., $\boldsymbol{h}_i \sim \mathcal{CN}(\mathbf{0}, \boldsymbol{I})$. The average transmit signal-to-noise-ratio (SNR) P_0/σ^2 is chosen as 20 dB. We assume that all devices have the same number of data points, i.e., $|\mathcal{D}_1| = \cdots = |\mathcal{D}_M|$, for which the pre-processing post-processing pair can be chosen as $\phi_i = 1, \psi = 1/|\mathcal{S}|$.

A. Probability of Feasibility

Consider the network with M=20 mobile devices and the BS is equipped with N=6 antennas. As a critical step for the device selection, the performance of feasibility detection with the proposed DC approach by solving \mathcal{P}_{S2} shall be compared with the following state-of-the-art approaches:

- **SDR** [25]: Simply dropping the rank-one constraint of problem (24) yields the semidefinite relaxation (SDR) approach for the feasibility detection problem.
- Global Optimization [46]: In [46], a global optimization approach is proposed with exponential time complexity in the worst case. We set the relative error tolerance as $\epsilon=10^{-5}$ and take its performance as our benchmark.

The results averaged over 100 times are shown in Fig. 4, which demonstrates that the proposed DC-based approach outperforms SDR approach significantly and achieves the near-optimal performance compared with the global optimization approach, and thus yields accurate feasibility detection.

We then evaluate the performance of the proposed DC approach over the number of antennas. Under different target MSE requirement, the results averaged over 100 channel realizations are illustrated in Fig. 5. It demonstrates that fast aggregation from mobile devices under a more stringent MSE requirement can be accomplished by increasing the number of antennas at the BS.

B. Number of Selected Devices over Target MSE

Consider a network with 20 mobile devices and a 6-antenna BS. Under the presented two-step framework and ordering rule in Algorithm 2, we compare the proposed DC Algorithm 2 for device selection with the following state-of-the-art approaches:

Fig. 4: Probability of feasibility with different algorithms.

Fig. 5: Probability of feasibility over the number of BS antennas with the proposed DC approach.

- ℓ_1 +SDR [39] [25]: The ℓ_1 -norm minimization is adopted to induce the sparsity of x in Step 1, and the nonconvex quadratic constraints are addressed with the SDR approach in Step 1 and Step 2.
- Reweighted ℓ_2 +SDR [26]: We take the smoothed ℓ_p norm for sparsity inducing of x in Step 1, which is
 solved by the reweighted ℓ_2 -minimization algorithm. The
 SDR approach is used to address the nonconvex quadratic
 program in Step 1 and Step 2.

The average results over 100 channel realizations with different approaches for sparsity inducing and feasibility detection are illustrated in Fig. 6. It is demonstrated that the novel sparsity and low-rankness inducing approach via the proposed DC algorithm is able to select more devices than other state-of-the-art approaches.

C. Performance of Proposed DC Approach for Distributed Federated Learning

To show the performance of the proposed DC approach for device selection in distributed federated learning, we further train a support vector machine (SVM) classifier on CIFAR-10 dataset [31] with a 6-antenna BS and 20 mobile devices. CIFAR-10 is a commonly used dataset of images for

Fig. 6: Average number of selected devices with different algorithms.

classification and contains 10 different classes of objects. The benchmark is chosen as the case where all devices are selected and all local updates are aggregated without aggregation error. We average over 10 channel realizations and the performances of all algorithms with $\gamma=5{\rm dB}$ are illustrated in Fig. 7. The relative accuracy is defined by the test accuracy over random classification. The simulation results demonstrate that the proposed DC approach achieves lower training loss and higher prediction accuracy as shown in Fig. 7a and Fig. 7b, respectively.

VII. CONCLUSION

In this paper, we proposed a novel fast global model aggregation approach for federated learning based on the principles of over-the-air computation. To improve the statistical learning performance for on-device distributed training, we developed a novel sparse and low-rank modeling approach to maximize the selected devices with the MSE requirements for model aggregation. We provided a unified DC representation framework to induce sparsity and low-rankness, which is supported by the convergence guaranteed DC algorithm via successive convex relaxation. Simulation results demonstrated the admirable performance of the proposed approaches compared with the state-of-the-art algorithms.

There are still some interesting open problems on the fast model aggregation for on-device federated learning including:

- This work assumes the perfect channel state information during receiver beamforming. It would be interesting to investigate the impacts of channel uncertainty in model aggregation.
- The security issues are also critical for model aggregation, though it is beyond the scope of this paper. It is also interesting to propose a robust approach against the malicious attacks during model aggregation.
- The proposed DC approach for feasibility detection has comparable performance with the global optimization approach through numerical experiments. But it remains challenging to characterize its optimality conditions of the DC approach.

APPENDIX A PROOF OF PROPOSITION 1

The sequence $\{b_i\}$ given by Proposition 1 has the zeroforcing structure which enforces

$$\sum_{i \in \mathcal{S}} \left| \boldsymbol{m}^{\mathsf{H}} \boldsymbol{h}_i b_i - \phi_i \right|^2 = 0. \tag{50}$$

In addition, the MSE satisfies

$$\mathsf{MSE}(\hat{g}, g) \ge \sigma^2 \|\boldsymbol{m}\|^2. \tag{51}$$

Therefore, the MSE is minimized by the zero-forcing transmitter beamforming vectors $\{b_i\}$'s given in Proposition 1.

APPENDIX B PROOF OF PROPOSITION 5

Without loss of generality, we shall only present the proof of properties (i) and (ii), while properties (iii) and (iv) can be proved with the same merit. For the sequence $\{(\boldsymbol{M}^{[t]}, \boldsymbol{x}^{[t]})\}$ generated by iteratively solving problem (40), we denote the

dual variables as $Y_M^{[t]} \in \partial_{M^{[t]}} h_1, Y_x^{[t]} \in \partial_{x^{[t]}} h_1$. Due to the strong convexity of h_1 , we have

$$h_{1}^{[t+1]} - h_{1}^{[t]} \ge \langle \Delta_{t} \boldsymbol{M}, \boldsymbol{Y}_{M}^{[t]} \rangle + \langle \Delta_{t} \boldsymbol{x}, \boldsymbol{Y}_{x}^{[t]} \rangle + \frac{\alpha}{2} (\|\Delta_{t} \boldsymbol{M}\|_{F}^{2} + \|\Delta_{t} \boldsymbol{x}\|_{2}^{2}),$$
 (52)

$$\langle \boldsymbol{M}^{[t]}, \boldsymbol{Y}_{M}^{[t]} \rangle + \langle \boldsymbol{x}^{[t]}, \boldsymbol{Y}_{x}^{[t]} \rangle = h_{1}^{[t]} + h_{1}^{*[t]},$$
 (53)

where $\Delta_t \boldsymbol{M} = \boldsymbol{M}^{[t+1]} - \boldsymbol{M}^{[t]}$ and $\Delta_t \boldsymbol{x} = \boldsymbol{x}^{[t+1]} - \boldsymbol{x}^{[t]}$. Adding $g_1^{[t+1]}$ at both sides of (52), we obtain that

$$f_1^{[t+1]} \leq g_1^{[t+1]} - h_1^{[t]} - \langle \Delta_t \boldsymbol{M}, \boldsymbol{Y}_M^{[t]} \rangle + \langle \Delta_t \boldsymbol{x}, \boldsymbol{Y}_x^{[t]} \rangle - \frac{\alpha}{2} (\|\Delta_t \boldsymbol{M}\|_F^2 + \|\Delta_t \boldsymbol{x}\|_2^2).$$
 (54)

For the update of primal variable M and x according to equation (38), we have $Y_M^{[t]} \in \partial_{M^{[t+1]}} g_1, Y_x^{[t]} \in \partial_{x^{[t+1]}} g_1$. This implies that

$$g_1^{[t]} - g_1^{[t+1]} \ge \langle -\Delta_t \boldsymbol{M}, \boldsymbol{Y}_M^{[t]} \rangle + \langle -\Delta_t \boldsymbol{x}, \boldsymbol{Y}_x^{[t]} \rangle + \frac{\alpha}{2} (\|\Delta_t \boldsymbol{M}\|_F^2 + \|\Delta_t \boldsymbol{x}\|_2^2),$$
 (55)

$$\langle \boldsymbol{M}^{[t+1]}, \boldsymbol{Y}_{M}^{[t]} \rangle + \langle \boldsymbol{x}^{[t+1]}, \boldsymbol{Y}_{x}^{[t]} \rangle = g_{1}^{[t+1]} + g_{1}^{*[t]}.$$
 (56)

Similarly, by adding $-h_1^{[t]}$ at both sides of equation (55), we have

$$f_1^{[t]} \ge g_1^{[t+1]} - h_1^{[t]} + \langle -\Delta_t \boldsymbol{M}, \boldsymbol{Y}_M^{[t]} \rangle + \langle -\Delta_t \boldsymbol{x}, \boldsymbol{Y}_x^{[t]} \rangle + \frac{\alpha}{2} (\|\Delta_t \boldsymbol{M}\|_F^2 + \|\Delta_t \boldsymbol{x}\|_2^2).$$

$$(57)$$

From equation (53) and equation (56), we deduce that

$$g_1^{[t+1]} - h_1^{[t]} + \langle -\Delta_t M, Y_M^{[t]} \rangle + \langle -\Delta_t x, Y_x^{[t]} \rangle = f_1^{*[t]},$$
 (58)

where $f_1^* = h_1^* - g_1^*$. Combining equation (54), (57) and (58), it is derived that

$$f_1^{[t]} \ge f_1^{*[t]} + \frac{\alpha}{2} (\|\Delta_t M\|_F^2 + \|\Delta_t x\|_2^2)$$
 (59)

$$\geq f_1^{[t+1]} + \alpha (\|\Delta_t \boldsymbol{M}\|_F^2 + \|\Delta_t \boldsymbol{x}\|_2^2). \tag{60}$$

Then the sequence $\{f_1^{[t]}\}$ is non-increasing. Since $f_1 \geq 0$ always holds, we conclude that the sequence $\{f_1^{[t]}\}$ is strictly decreasing until convergence, i.e.,

$$\lim_{t \to \infty} (\|\boldsymbol{M}^{[t]} - \boldsymbol{M}^{[t+1]}\|_F^2 + \|\boldsymbol{x}^{[t]} - \boldsymbol{x}^{[t+1]}\|_2^2) = 0. \quad (61)$$

For every limit point, $f_1^{[t+1]} = f_1^{[t]}$, we have

$$\|\boldsymbol{M}^{[t]} - \boldsymbol{M}^{[t+1]}\|_F^2 = 0, \|\boldsymbol{x}^{[t]} - \boldsymbol{x}^{[t+1]}\|_2^2 = 0,$$
 (62)

and

$$f^{[t+1]} = f^{*[t]} = f^{[t]}. (63)$$

Then it is followed by

$$h^{*[t]} + h^{[t+1]} = g^{[t]} + g^{[t+1]}$$

$$= \langle \mathbf{M}^{[t+1]}, \mathbf{Y}_{M}^{[t]} \rangle + \langle \mathbf{x}^{[t+1]}, \mathbf{Y}_{x}^{[t]} \rangle, \qquad (64)$$

i.e.,

$$Y_M^{[t]} \in \partial_{M^{[t+1]}} h_1, Y_T^{[t]} \in \partial_{T^{[t+1]}} h_1.$$
 (65)

Therefore, $Y_M^{[t]} \in \partial_{M^{[t+1]}} g_1 \cap \partial_{M^{[t+1]}} h_1$, $Y_x^{[t]} \in \partial_{x^{[t+1]}} g_1 \cap \partial_{x^{[t+1]}} h_1$. It is concluded that $(M^{[t+1]}, x^{[t+1]})$ is a critical point of $f_1 = g_1 - h_1$. In addition, since

$$\operatorname{Avg}\left(\|\boldsymbol{M}^{[t]} - \boldsymbol{M}^{[t+1]}\|_F^2 + \|\boldsymbol{x}^{[t]} - \boldsymbol{x}^{[t+1]}\|_2^2\right) \\ \leq \sum_{i=0}^t \frac{1}{\alpha(t+1)} (f_1^{[i]} - f_1^{[i+1]}) \tag{66}$$

$$\leq \frac{1}{\alpha(t+1)} (f_1^{[0]} - f_1^{[t+1]}) \tag{67}$$

$$\leq \frac{1}{\alpha(t+1)} (f_1^{[0]} - f_1^{\star}),$$
(68)

we conclude that property (ii) holds, i.e.,

$$\operatorname{Avg}\left(\|\boldsymbol{M}^{[t]} - \boldsymbol{M}^{[t+1]}\|_F^2\right) \le \frac{f_1^{[0]} - f_1^{\star}}{\alpha(t+1)},\tag{69}$$

$$\operatorname{Avg}\left(\|\boldsymbol{x}^{[t]} - \boldsymbol{x}^{[t+1]}\|_{2}^{2}\right) \le \frac{f_{1}^{[0]} - f_{1}^{\star}}{\alpha(t+1)}.\tag{70}$$
